

How much did restricting mobility help in controlling the spread of COVID?

Satheesh Joseph, Paco Valdez, Yi Zhang

Introduction

Overview

The Covid-19 pandemic has taken more than 2.5 million lives worldwide. In the U.S. alone, more than half a million people died because of it. COVID-19 is thought to spread mainly through close contact from person to person, including among people who are physically near each other (within about 6 feet).[1]

As the virus spread, many cities and other areas have implemented a shutdown policy that significantly restricted the mobility of the population. Specifically, many companies have opted for a complete work-from-home policy.

As a team of Data Scientists, we're interested in assessing the effectiveness of restricting mobility in controlling the spread of Covid-19.

Research Question

Rather than investigating the effect of social distancing on a micro and personal interaction level, we are interested in its effect on a policy level. Specifically, the Research Question we're asking is:

How much did restricting social mobility help in controlling the spread of COVID?

The basic causal theory we're working under can be expressed by the diagram below:

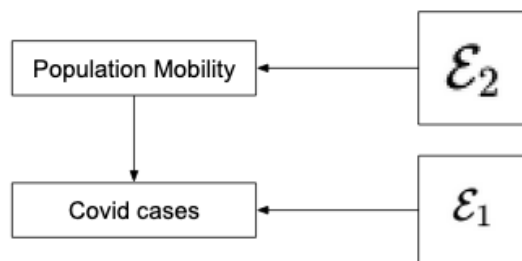

Figure 1: The Basic Causal Theory

Operationalization

To operationalize the research question, we propose the following plan for the causal models.

Firstly, we will use the New York Times[2] Covid-19 data for the number of Covid cases per State. And we will use the Covid-19 Community Mobility Report[3] for the population mobility scores. For the base model,

we will use the “residential mobility score” as a relatively stable representative of the general population’s social mobility.

Secondly, mobility have drastically different effect on the spread of the virus depending on the population density. Thus, we believe that having the raw number of cases as the outcome variable can be misleading. Therefore, we will be using the number of cases per 100,000 residents as the outcome variable to normalize the population density. The population density data will come from the COVID-19 US State Policy Database[4].

More formally, our base model will assume a causal relationship of the form:

$$cases_per_100k_residents = \beta_0 + \beta_1 residential_mobility_score$$

where each data point will represent a State in the U.S., and the outcome variable will be the total number of Covid-19 cases per 100,000 residents for that state since 2020-02-15 up until 2020-07-15, when the mask wearing survey[5] was taken. And the independent variable will be the **average** residential mobility score of the state in the time period.

For a more advanced model, we propose to use some control variables to assess the difference mobility score makes in relation to other factors, notably we’ll include whether the “Stay at Home” order is in effect and whether the face mask policy is in effect and how long has been in place.

The mask wearing survey data will be operationalized by transforming it into probability of people wearing mask. The probability of people wears masks is calculated by assuming that survey respondents who answered ‘Always’ were wearing masks all of the time, those who answered ‘Frequently’ were wearing masks 80 percent of the time, those who answered ‘Sometimes’ were wearing masks 50 percent of the time, those who answered ‘Rarely’ were wearing masks 20 percent of the time and those who answered ‘Never’ were wearing masks none of the time.

For the most inclusive model, we will explore all the other mobility scores, including to workplaces, transit, parks, grocery & pharmacy.

The models

Data Exploration

##	state	cases_per_100k	workplaces	transit

All the variables have their means and medians very close to each other, that suggests that there is no severe skewness.

The histogram plots below shows no major deviation from normality for the variables.

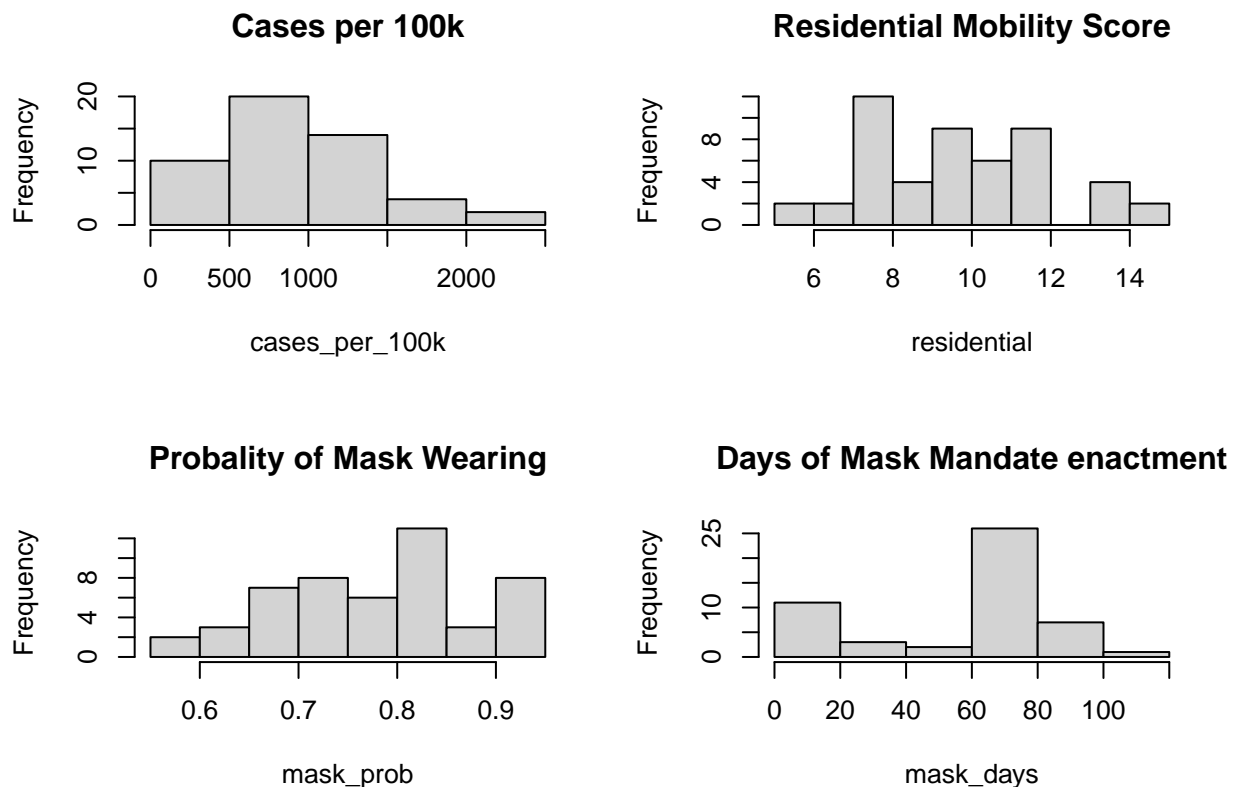

Figure 2: Histograms of the left-hand side variable and selected right-hand side variables

The other mobility variables also doesn't show major deviation from normality.

Using natural logarithm transformation on the variables doesn't show a significant improvement. We will continue the analysis without the transformation.

By looking at the scatter plots we can notice that **workplaces** is the inverse of the **residential** mobility variable. Using both in a OLS regression probably will cause the coefficients to cancel each other. The **residential** variable shows promising results, it looks like it has a very linear relationship with **cases_per_100k**.

The Linear Models

Our intuition told us that the residential variable would be the best proxy to represent mobility. At this point in time during the pandemic, the U.S. was registering its second wave of Covid-19 cases and non-essential business were still closed in most of the states. One way to explain this relationship is that in the states where the residential mobility score increased, people were not sheltering at their homes. Instead people were going out with friends and family, thus spreading the virus.

Model One

In our initial model we will use the residential mobility score and cases per 100,000 inhabitants:

$$cases_per_100k_residents = \beta_0 + \beta_1 residential_mobility_score$$

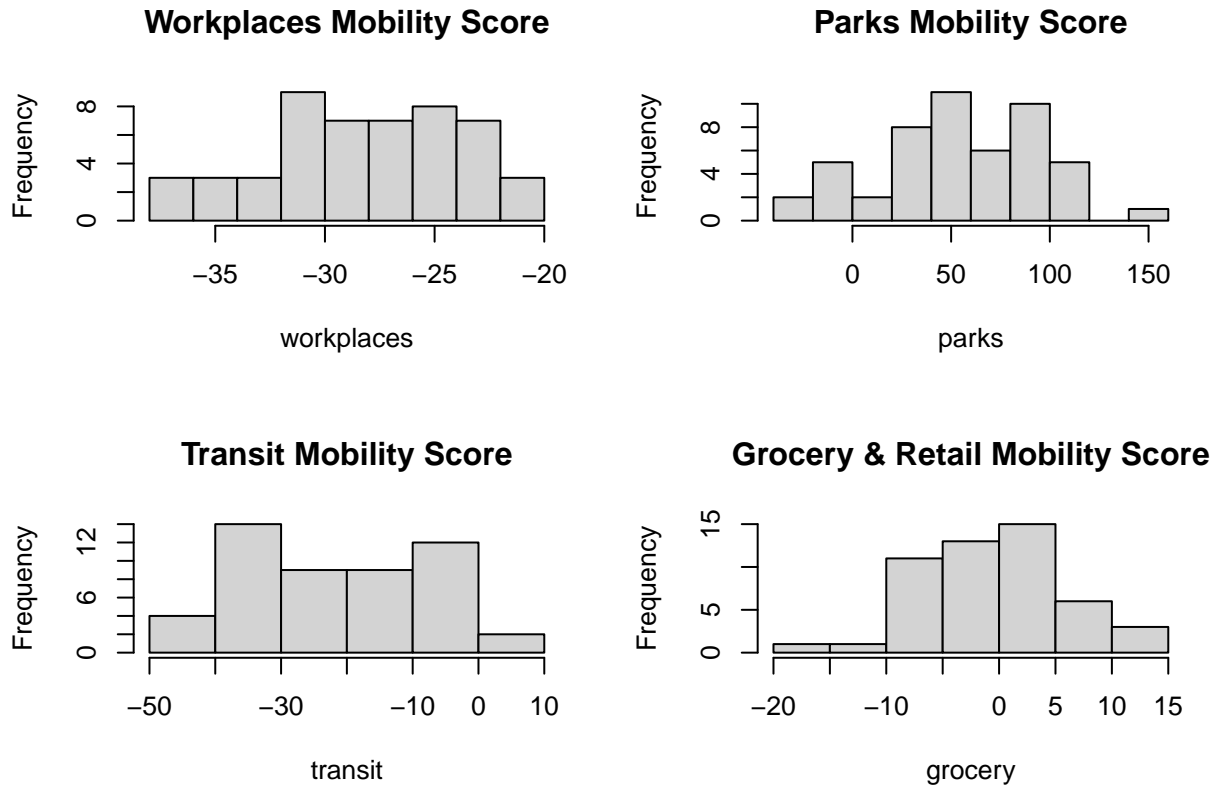

Figure 3: Histograms of the mobility variables

```
##
## Call:
## lm(formula = cases_per_100k ~ residential, data = data)
##
## Residuals:
##      Min       1Q   Median       3Q      Max
## -1156.38  -277.06   -29.98   314.56   946.99
##
## Coefficients:
##              Estimate Std. Error t value Pr(>|t|)
## (Intercept)   -9.003     272.637  -0.033  0.97379
## residential    95.801      27.466   3.488  0.00105 **
## ---
## Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
##
## Residual standard error: 437.7 on 48 degrees of freedom
## Multiple R-squared:  0.2022, Adjusted R-squared:  0.1856
## F-statistic: 12.17 on 1 and 48 DF,  p-value: 0.001052
```

We got a very significant p-value, which highlights the strong relationship between these two variables. The first control variable we will introduce is the face-mask mandate (`fm`). It did not reduce the significance of the mobility variable and it showed no significant effect on the dependent variable.

$$\text{cases_per_100k_residents} = \beta_0 + \beta_1 \text{residential_mobility_score} + \beta_2 \text{face_mask_mandate}$$

```
##
## Call:
```

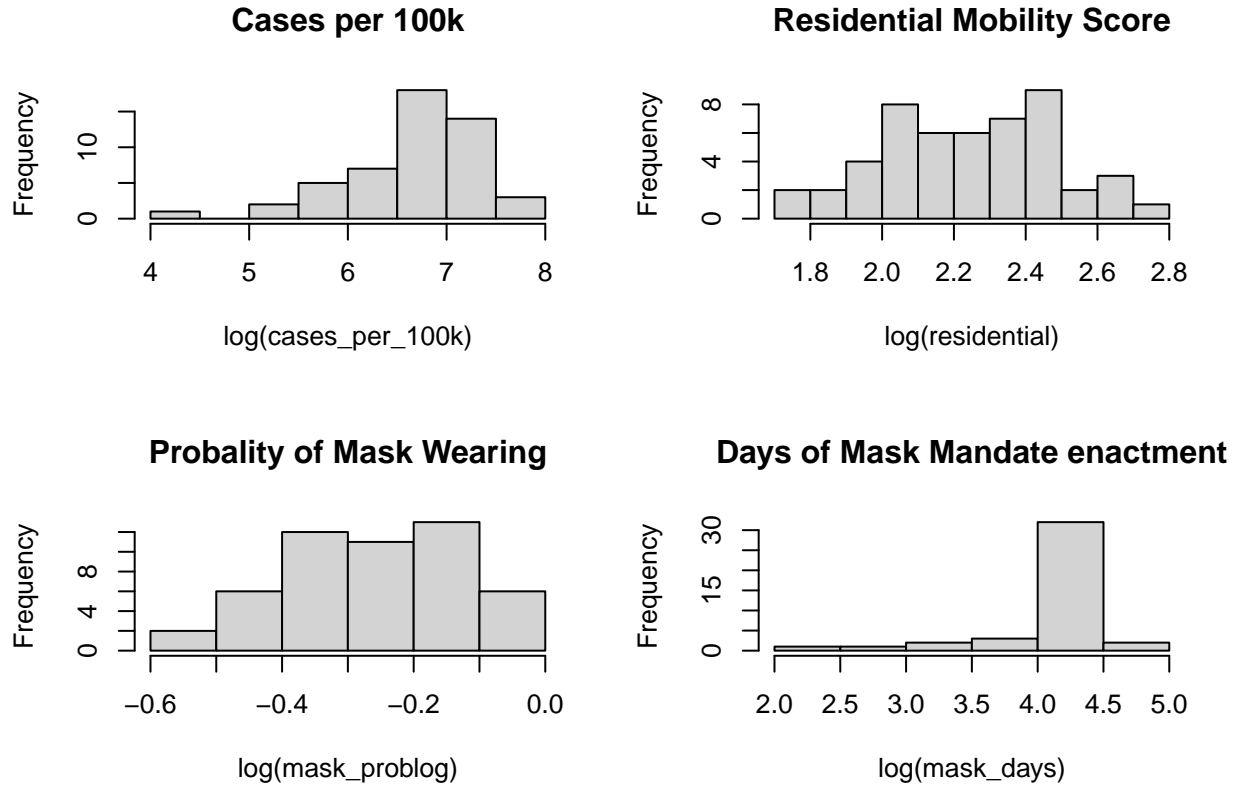

Figure 4: Histograms of selected log-transformed variables

```
## lm(formula = cases_per_100k ~ residential + fm, data = data)
##
## Residuals:
##      Min       1Q   Median       3Q      Max
## -1165.63  -278.95   -32.79   321.18   971.17
##
## Coefficients:
##              Estimate Std. Error t value Pr(>|t|)
## (Intercept)    -1.51     274.81  -0.005  0.99564
## residential    104.12     31.06   3.352  0.00159 **
## fm           -107.19    182.21  -0.588  0.55917
## ---
## Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
##
## Residual standard error: 440.7 on 47 degrees of freedom
## Multiple R-squared:  0.208, Adjusted R-squared:  0.1743
## F-statistic: 6.173 on 2 and 47 DF, p-value: 0.004165
```

The second control variable is if the state had a stay at home order effective on the same time frame. This control variable again did not reduce the significance of the residential mobility score and also is not significant.

$$\text{cases_per_100k_residents} = \beta_0 + \beta_1 \text{residential_mobility_score} + \beta_2 \text{face_mask_mandate} + \beta_3 \text{stay_at_home_order}$$

```
##
## Call:
## lm(formula = cases_per_100k ~ residential + fm + stay_home, data = data)
##
```

Figure 5: Scatter Plots for Cases per 100k and selected mobility variables

```
## Residuals:

## Multiple R-squared:  0.2162, Adjusted R-squared:  0.1651
## F-statistic: 4.231 on 3 and 46 DF,  p-value: 0.01008
```

Model Two

In the second model we wanted to test if the probability of wearing a mask would have a significant impact on the amount of Covid-19 cases. Although by looking at the scatter plot of Cases per 100k and mask wearing probability there is no clear relationship, and the slope of the OLS line has the opposite direction to what our intuition tell us.

So, our second model contains the residential mobility score and the face mask wearing probability. The coefficient for Mask wearing probability (`mask_prob`), at least has the correct direction but fails to achieve

Figure 6: Scatter Plots for Cases per 100k and selected mobility variables with OLS regression line and standard errors

significance. The residential mobility score coefficient is still significant, which give us more trust in that variable.

$$cases_per_100k_residents = \beta_0 + \beta_1 residential_mobility_score + \beta_2 mask_wearing_probability$$

```
##
## Call:
## lm(formula = cases_per_100k ~ residential + mask_prob, data = data)
##
## Residuals:
##      Min       1Q   Median       3Q      Max
## -1157.95  -275.90   -29.57   317.37   946.76
##
## Coefficients:
##              Estimate Std. Error t value Pr(>|t|)
## (Intercept)   -28.90     566.30  -0.051  0.9595
## residential    94.27     47.11   2.001  0.0512 .
## mask_prob     44.71    1111.62  0.040  0.9681
## ---
## Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
##
## Residual standard error: 442.3 on 47 degrees of freedom
## Multiple R-squared:  0.2022, Adjusted R-squared:  0.1683
## F-statistic: 5.957 on 2 and 47 DF,  p-value: 0.004945
```

Again, we can test our previous control variables. Even with the presence of the other control variables the

Figure 7: Scatter Plots for Cases per 100k and mask wearing probability

residential mobility score coefficient is still significant.

$$cases_per_100k_residents = \beta_0 + \beta_1 residential_mobility_score + \beta_2 mask_wearing_probability + \beta_3 face_mask_mandat$$

```
##
## Call:
## lm(formula = cases_per_100k ~ residential + mask_prob + fm +
##     stay_home, data = data)
##
## Residuals:
##      Min       1Q   Median       3Q      Max
## -1182.73  -258.03   -51.08   266.09  1007.37
##
## Coefficients:
##              Estimate Std. Error t value Pr(>|t|)
## (Intercept)   -195.68    597.38  -0.328   0.745
## residential     96.33     47.83   2.014   0.050 *
## mask_prob     504.64   1216.47   0.415   0.680
## fm            -131.99    192.71  -0.685   0.497
## stay_home     -130.59    167.90  -0.778   0.441
## ---
## Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
##
## Residual standard error: 447.2 on 45 degrees of freedom
```

```
## Multiple R-squared:  0.2192, Adjusted R-squared:  0.1498
## F-statistic: 3.159 on 4 and 45 DF,  p-value: 0.02265
```

Model Three

Our secondary question was if the other mobility variables could have a significant impact on the cases per 100,000 variable. In our data exploration, workplaces also looked promising but it looked that it acted in the opposite direction than residential. When we tested this variable alone we confirmed our intuition, the workplaces mobility score is also significant but acts in the opposite direction than residential.

$$cases_per_100k_residents = \beta_0 + \beta_1 workplaces_mobility_score$$

```
##
## Call:
## lm(formula = cases_per_100k ~ workplaces, data = data)
##
## Residuals:
##      Min       1Q   Median       3Q      Max
## -964.49 -309.07  -40.55   358.81   967.50
##
## Coefficients:
##              Estimate Std. Error t value Pr(>|t|)
## (Intercept)  -200.07     422.11  -0.474   0.6377
## workplaces    -39.76      14.85  -2.678   0.0101 *
## ---
## Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
##
## Residual standard error: 457.1 on 48 degrees of freedom
## Multiple R-squared:  0.13, Adjusted R-squared:  0.1119
## F-statistic: 7.173 on 1 and 48 DF,  p-value: 0.0101
```

When both are present residential still has a more significant effect. And the coefficient for workplaces mobility score is significantly lower and in the opposite direction than the previous model.

$$cases_per_100k_residents = \beta_0 + \beta_1 residential_mobility_score + \beta_2 workplaces_mobility_score$$

```
##
## Call:
## lm(formula = cases_per_100k ~ residential + workplaces, data = data)
##
## Residuals:
##      Min       1Q   Median       3Q      Max
## -1281.37 -270.89  -45.09   295.65   932.94
##
## Coefficients:
##              Estimate Std. Error t value Pr(>|t|)
## (Intercept)   485.43     492.39   0.986   0.3292
## residential   178.37      73.86   2.415   0.0197 *
## workplaces    46.01      38.23   1.203   0.2348
## ---
## Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
##
## Residual standard error: 435.7 on 47 degrees of freedom
## Multiple R-squared:  0.2261, Adjusted R-squared:  0.1931
```

F-statistic: 6.864 on 2 and 47 DF, p-value: 0.002425

Our definitive third model is the comparison of all the mobility score variables, with the exception of the workplaces variable since it's the opposite of residential. The residential mobility score captures the information contained in the other mobility variables.

$$\text{cases_per_100k_residents} = \beta_0 + \beta_1 \text{residential_mobility_score} + \beta_2 \text{parks_mobility_score} + \beta_3 \text{grocery_mobility_score} +$$

```
##
## Call:
## lm(formula = cases_per_100k ~ residential + parks + grocery +
##     transit, data = data)
##
## Residuals:
##      Min       1Q   Median       3Q      Max
## -962.05 -331.49  -35.52   287.97   974.35
##
## Coefficients:
##              Estimate Std. Error t value Pr(>|t|)
## (Intercept)  -741.685     512.163  -1.448  0.15451
## residential   205.745      67.116   3.066  0.00367 **
## parks         -3.705       1.879  -1.972  0.05478 .
## grocery       46.363      22.245   2.084  0.04285 *
## transit        4.830      10.768   0.449  0.65591
## ---
## Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
##
## Residual standard error: 421.8 on 45 degrees of freedom
## Multiple R-squared:  0.3055, Adjusted R-squared:  0.2438
## F-statistic: 4.949 on 4 and 45 DF, p-value: 0.002156
```

We can also add our control variables to the previous model.

$$\text{cases_per_100k_residents} = \beta_0 + \beta_1 \text{residential_mobility_score} + \beta_2 \text{parks_mobility_score} + \beta_3 \text{grocery_mobility_score} +$$

```
##
## Call:
## lm(formula = cases_per_100k ~ residential + parks + grocery +
##     transit + fm + stay_home, data = data)
##
## Residuals:
##      Min       1Q   Median       3Q      Max
## -981.87 -321.63  -54.48   285.89   974.64
##
## Coefficients:
##              Estimate Std. Error t value Pr(>|t|)
## (Intercept)  -692.225     600.679  -1.152  0.25552
## residential   204.577      70.082   2.919  0.00557 **
## parks         -3.718       1.923  -1.933  0.05978 .
## grocery       44.643      24.632   1.812  0.07691 .
## transit        4.691      11.136   0.421  0.67568
## fm          -35.676     190.458  -0.187  0.85229
## stay_home    -15.649     170.565  -0.092  0.92732
```

```
## ---
## Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1
##
## Residual standard error: 431.3 on 43 degrees of freedom
## Multiple R-squared:  0.3061, Adjusted R-squared:  0.2093
## F-statistic: 3.162 on 6 and 43 DF,  p-value: 0.0117
```

CLM assumptions

1. **IID Sampling** None of the variables seem to violate IID.

2. **Linear Conditional Expectation** By looking at the predicted vs. residuals of the model it looks that relationship is very linear.

Figure 8: Residuals vs Fitted plot for Model One

3. No Perfect Collinearity

```
## (Intercept) residential      parks      grocery      transit      fm
## -692.225365  204.577297  -3.718072  44.643304   4.690887 -35.675930
##   stay_home
##  -15.648967
```

None of the coefficients was dropped, that means there is no Perfect Collinearity.

4. **Homoskedastic Errors** The scale-location plot is very close to a flat line, which lead us to believe that there is no major issues with heteroskedasticity.

5. **Normally Distributed Errors** The histogram looks does not show a significant deviation from a normal distribution and the qqplot also shows very low deviation from normality.

Figure 9: Scale-Location plot for Model One

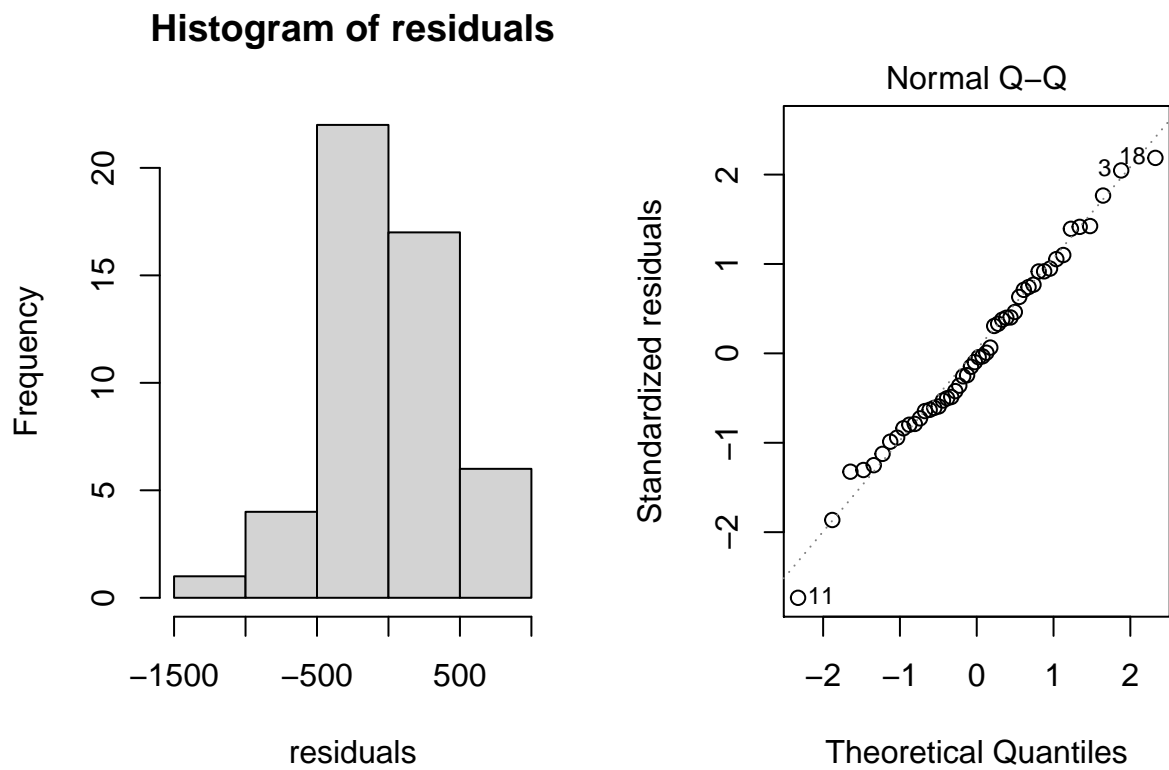

Figure 10: Histogram of residuals for model one and qq-plot for model one

In general we can say that all the 5 CLM Assumptions are met.

The Regression Table

Model Limitations

TimeSeries:

The Research Question under study is well suited for a time series analysis. The initial discussion and work, were poised to well take off in including a weekly average and correlation with the cases offset by couple of weeks. As per the instruction and the limited machinery in place, the team has decided to take an average for the states from a time window where all the variables were produced and use it in the model.

Reverse Causality:

The Research Question under study finds relationship between Mobility and COVID cases. But, there is also the reverse path where more COVID cases creates fear among people. Thus, people limiting outdoor activities.

All Percent drops are not equal:

A 10% drop in mobility is really good for sparsely populated regions to go below a certain threshold in transmitting the virus. The same cannot be applied to densely populated cities. Thus, the non-linearity in the measures taken vs impact seen is omitted.

Classic Linear Model assessment

Omitted Variables

Not following mandates:

Though, State and County put restrictions, including Mask mandate, Curfew, Social distance, Quarantine, park, school and restaurant closures, how much general public abide to these mandates is a very good [Omitted] indicator that influence the total cases. The omitted variable positively impacts outcome and positively related with measured variable, thus moving away from zero.

International/Non-Local Mobility:

As we all know Port of Entries like New York, San Francisco, Chicago and Seattle are the first affected places. State wide policies restricting mobility has varying effects on how close a location is to the airport or other transit points. Thus, closeness to transit stations and airport is an omitted variable. The omitted variable positively impacts outcome and positively related with measured variable, thus moving away from zero.

Conclusion
